<sup>2</sup> Supervisor, School of Heath Sciences, British Columbia Institute of Technology, 3700 Willingdon Ave, Burnaby, BC V5G 3H2

**Abstract:** Cantaloupe melon was the source of a lethal outbreak of *Listeria* in 2011. This research investigated whether washing a contaminated cantaloupe rind was sufficient in preventing the transferring of *Escherichia coli*. Hence, the null hypothesis for this study was that there is no association between washing a contaminated cantaloupe melon and the presence of the contamination in the flesh. In this study, 10 cantaloupes were used to produce a sample size of 20 per washed and unwashed treatments. Each of the samples was transferred to EC broth to determine the presence and absence of *Escherichia coli* (E. coli), the indicator organism that acted as the “outbreak contaminant.” The results showed 100% of the unwashed melons and 80% of the washed melons to have E. coli transferred into the flesh. A Chi Square analysis produced a p-value of 0.035. The study determined that there was a statistically significant association between washing a melon and the presence of E. coli in the melon flesh. The author recommends washing melon rind as a means to prevent foodborne illness caused by surface contaminants.

**Key Words:** Cantaloupe, melon, rind, flesh, outbreak, *Escherichia coli*, foodborne illness

## Introduction

The reason for this study is from an actual Listeria outbreak in cantaloupes in 2011. The outbreak was traced back to a farm in Colorado and it was determined that the contamination was from Listeria in the environment. This is relevant to public health because there are possible consumers who do not wash their melons and just cut into the fruits. The contamination from Listeria under this circumstance was not common, but may occur again. The ability of pathogenic and spoilage-causing bacteria to adhere to surfaces of melons does not only present a food safety problem, it also causes economic loss to the produce industry (Ukuku & Sapers, 2006a).

According to an article from the CFIA (2012), cantaloupe is one of the five commodities which have contributed to increased produce-associated foodborne disease outbreaks from 1998-2006. Hence, another reason for cantaloupe to be chosen is because this fresh produce is consumed raw and not subjected to a kill step during processing. Once these melons are available to the public, consumers become the last line of defence. This research will investigate if consumers are able to clean their melons before they cut into them, given that these melons are potentially contaminated.

## Literature Review

### Legislation

Under the Canada Agricultural Products Act, the Fresh Fruit and Vegetable Regulations regulate cantaloupes. The legislation regulates the grade and standards, as well as general tolerances, which apply to cantaloupe varieties originating from *Cucum's melo* vat. *Cantalupensis*. The only acceptable grade for cantaloupe is Canada No. 1 (Fresh Fruit and Vegetable Regulation, 2013). The standard requires that the melon be “fairly clean, mature and sound” and free of any physical damages. As defined by the Canadian Food Inspection Agency (2011), fairly clean refers to the melon when it does not show any noticeable dirt or foreign material that affects its appearance. In addition, under section 30 of the Regulation, it states that Canada No. 1 graded cantaloupes shall “be free from insects, insect larvae, insect damage and disease.”

### Mode of microbial contamination to cantaloupes

The predominant class of organisms on cantaloupe melon is aerobic mesophilic bacteria followed by lactic acid bacteria, Gram-negative bacteria, yeasts and moulds, and *Pseudomonas* spp. (Ukuku & Fett, 2002). The rind of a cantaloupe provides a perfect surface for microorganisms to attach to. The external surface is characterized by a

net comprising porous lenticel tissue (Webster & Craig, 1976). Merriam-Webster (2013) defines lenticel tissues as “a loose aggregation of cells which penetrates the surface of a woody plant...where gases are exchanged between the atmosphere and the underlying tissue.” This material provides attachment sites for microorganisms and also a shield for the attached cells when the surface is cleaned (Ukuku & Sapers, 2006b).

### Sources of contamination

Cantaloupes can be contaminated during their growth, harvesting, processing, transportation, or preparation, if not handled properly by the food handler (CFIA, 2012). Many of the common sources of contamination are illustrated in Figure 1, below.

Preharvest contamination of melons with human pathogens may be the result from the use of sewage-contaminated irrigation water (FDA, 2003). Irrigation water, transported over long distances and distributed to farms through open and unprotected aqueducts, may become contaminated by surrounding activities (FDA, 2003). Other possible sources of contamination may originate from the feces of birds, reptiles, and other wildlife in the area (Clark & McLean, 2003).

Post harvest contamination is one common source of contamination for melons. There have been incidences of cantaloupe melons where they have been found to have an increased concentration of indicator organisms on the melons during washing. Gagliardi *et al.* (2003) attributed the contamination to the management of primary wash tanks, such as the use of contaminated river water; build up of soils in tanks, and the depletion of chlorine. Ukuku & Sapers (2006c) have observed melon processing operations in which cantaloupes were packed too tightly in wash tanks containing chlorinated water. The tight packing minimizes any opportunity for agitation of the melons or mixing of water. Additional sources of post harvest contamination include poor personal hygiene or work practices and inadequate plant sanitation (Ukuku & Sapers, 2006c). Inadequately sanitized conveyor systems may permit debris to accumulate and microbial populations to build up on food contact surfaces; therefore, it is important to sanitize equipments on a regular schedule with sufficient frequency (Ukuku & Sapers, 2006c).

### Potential Sources of Melon Contamination

#### Preharvest

- Direct fecal contamination — human, birds, reptiles, insects, other wildlife
- Indirect fecal contamination — irrigation water, dust from animal production

#### During harvest

- Poor worker hygiene

#### Packing plant

- Contaminated process water
- Poor plant sanitation
- Ineffective washing
- Cross contamination during washing
- Poor worker hygiene

Figure 1. Summary for Sources of Contamination, Adapted from Ukuku & Sapers (2006)

### Transfer of bacteria from rind to flesh

A crucial part of this research is to determine whether microorganisms are actually able to be transferred from the rind and into the flesh. In fact, there are past data that justify this scenario. Ukuku and Sapers (2001) and Ukuku and Fett (2002) inoculated cantaloupe with *Salmonella* and *Listeria*, respectively. The reports showed that the survival and transfer of the pathogens were positive and the population on fresh-cut pieces also survived and increased during temperature abused conditions.

### Ability to support growth

After being contaminated, the ability of the cantaloupe rind to support growth of the pathogens must be considered. The survival of such pathogens will permit them to proliferate to a concentration that is harmful to human health. Melon flesh is able to support the growth and survival of human pathogens, which include *Salmonella*, *E. coli O157:H7*, and *Listeria monocytogenes* (Ukuku & Sapers, 2006c).

Del-Rosario and Beuchat (1995) investigated the ability of *E. coli O157:H7* to survive and grow on the flesh and external rind surface of cantaloupe melons. In their study they found that the pathogen was able to survive and proliferate at 25°C on the melon flesh, during a 34 hour storage period. However, the concentration of the pathogen on the melon flesh (inside of the melon) remained constant at 5°C during the same time period. In another test, they observed the rind of cantaloupes and found that the growth of the pathogen was also present at 25°C for 14-22 days. The major difference in this version of the test was that the pathogen rapidly died on the rind surface (outside surface of the melon) when it was stored at 5°C.

In a research conducted by Golden *et al.* (1993), the ability of *Salmonella* spp. to grow on rind-free pieces of melons was studied. They tested cantaloupe, watermelon and honeydew, with pH values that ranged from 5.90 – 6.67. In another study, Nyguyen *et al.* (2012) from the University of Florida found the

pH of fresh cut cantaloupe to be 7.01. The FDA food code considers the cantaloupe as a potentially hazardous food because it is capable of supporting the growth of pathogens due to its pH being 5.2-6.7 and high water activity between 0.97 and 0.99. The near neutral pH of the inner flesh and availability of nutrients heightened the survival of pathogens in cantaloupe (Richards and Beuchat, 2004). Consequently, the results from Golden *et al.* (1993) indicated that *Salmonella* growth was rapid and prolific on the melons at 23°C. Similar to the study by Del-Rosario and Beuchat (1995), the *Salmonella* population did not increase during the 24 hour incubation at 5°C.

Further evidence provided by Bhagwat (2006) supports the fact that the transfer of bacteria from the rind to edible melon flesh can occur. *Salmonella* spp. and *E. coli* O157:H7 are able to proliferate to hazardous levels on cut melons stored at ambient temperature.

### **Control measures**

When the rind of cantaloupe melons is contaminated, it becomes difficult to clean because of the rough netted surface. This characteristic of the rind provides areas for bacterial attachment and protection from cleaning and sanitization (CFIA, 2012). In a comparison study done by Park and Beuchat (1999) they reported that greater numbers of *E. coli* and *Salmonella* cells were deactivated or removed from inoculated honeydew melon than from cantaloupe when the melons were washed with sanitizer solutions. When 200-2000ppm chlorine solution was used, the microorganisms found on honeydew melon were reduced to lower levels than the population on cantaloupes (Park & Beuchat, 1999). From these results, it seems like chlorine solution may be an option to effectively disinfect store bought cantaloupes that may have been subject to contamination.

Due to the difficulty of supplying adequate water to mobile washing equipment, field-packed melons are generally not washed. The melons that are transferred to packing plants may be immersed in a wash tank. It has been found by Gagliardi *et al.* (2003) that this method had minimal or no reduction and in some cases, an increase in microbial populations on cantaloupes and honeydew melons.

The effectiveness of other disinfectants such as chlorinated water and lactic acid were tested in a study done by Matheron (2003). In this experiment, he inoculated cantaloupes with *E. coli* O157:H7 and immersed the melons in disinfectants to decontaminate the melon. However, the results were

similar to Park and Beuchat where bacterial cells were reduced, but not eliminated. Matheron concludes by stating “The development of sanitizers more effective than chlorine for total elimination of this pathogen from the surface of cantaloupes is needed.”

Hot water is another method used for decontamination of whole cantaloupes. This method may be more practical for consumers because this resource is more easily accessible than commercial sanitizers. This method was able to significantly reduce microbiological populations on melon surfaces. The major advantage, which is also the focus of this research, was that it reduced the probability of potential transfer of pathogenic bacteria from the rind to the flesh during cutting (Ukuku *et al.*, 2004). According to Bhagwhat (2006), the most efficient method to remove microbes from the surfaces of melons was to scrub the surface with a clean brush under running water.

### **EHO's Involvement**

Health inspectors play a general role in the food safety aspect of fresh fruits, such as cantaloupes. An inspector has the role of ensuring the safety of all food that is sold and distributed through food premises (Manitoba Health, 2013). Any location or facility where food is prepared, stored or served to the general public is considered a food handling establishment (Manitoba Health, 2013). Some examples may include restaurants, grocery stores, and catering facilities; therefore, health inspectors have an important role in educating food handlers and consumers about safe food handling practices, such as removing surface contamination of fruits and vegetables (Fraser Health, 2011).

### **Methods**

An *E. coli* culture was enriched in TSA broth to prepare for the study. Over a 24 hour period at 35°C, the bacterial culture was enumerated to  $10^9$  cfu/ mL. Serial dilution was prepared by using a bottle filled with 99 ml of tap water. With this blank, the *E. coli* concentration was diluted to  $10^7$  cfu/mL. The diluted *E. coli* was further diluted in a bag, filled with 495 mL of tap water, to a concentration of  $10^5$  cfu/ mL. A negative control for the tap water and a positive control for the *E. coli* broth were plated.

Each whole cantaloupe melon was immersed into bags containing 500 mL of diluted “spiked” solution for five minutes. These melons were allowed to air

dry for 30 minutes at room temperature. Following the drying procedure, half of the melons were washed with hot running water and a scrubbing brush while the other half were left for cutting, without washing. The washed melons were allowed an additional 30 minutes for air drying.

Each of the melons were separated into quarters where 25g samples were drawn and transferred to individual stomacher bag where each sample was incubated at 35°C for 24 hours. From each bag, 1mL samples were transferred to EC broth tubes for standard fecal coliform testing. The procedure is summarized in Figure 2.

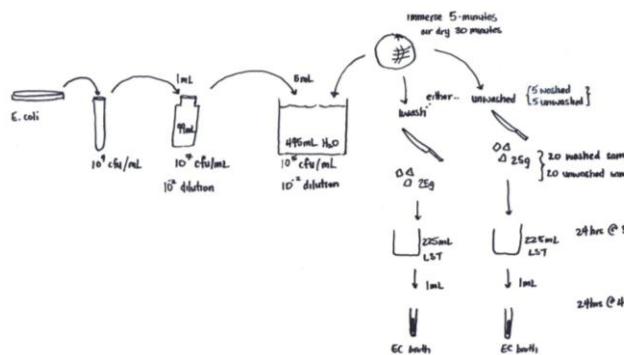

Figure 2: Flow diagram of procedure

## Results

### Description of data

The data collected from this study were counts of absence and presence of *E. coli* in melon flesh. This data was considered nominal and dichotomous, since the only two options were either present or absent (ENVH 8400 notes, 2013). The data originated from two sets of cantaloupes, each with a sample size of 20. The data represented the proportion of washed cantaloupes that contained contamination and the proportion of unwashed cantaloupes that contained contamination.

### Descriptive statistics

As in figure 3, 20/20 unwashed samples showed the presence of *E. coli*, whereas, in the washed samples 16/20 indicated presence.

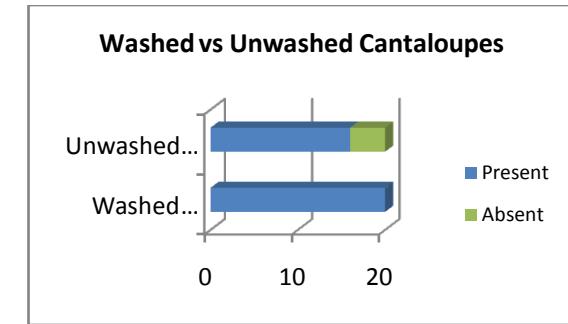

Figure 3: A Comparison of Washed and Unwashed Cantaloupes

### Inferential statistics

A chi-squared test was used to analyze the data collected from this study. This type of test is used to determine "...whether there is a difference in proportions of outcomes in two or more groups or whether there is an association between two or more groups" (ENVH 8400 notes, 2013). The test is only used on nominal data.

Hence, the null hypothesis for this study was that there is no association between washing a contaminated cantaloupe melon and the presence of the contamination in the flesh. Conversely, the alternative hypothesis stated that there is an association between washing a contaminated cantaloupe melon and the presence of the contamination in the flesh.

### Interpretation

The nominal data qualify as nonparametric as the testing of the hypothesis did not require normal distribution or variance assumptions about the populations from which the samples were drawn (Key, 1997).

Looking at the Pearson's Chi Square test, the p-value was 0.035; therefore, the null hypothesis was rejected at  $\alpha=0.05$  and it was concluded that washing melon rinds appears to reduce bacterial load on the rinds of cantaloupes. Based on that, there is an association between washing a melon and the presence of *E. coli* in the melon flesh (NCSS, 2013). However, because the p-value was not very low there is a chance of an alpha error. If an alpha error were to exist, the rejection of the null hypothesis would be incorrect and that there was, in fact, no association between washing of contaminated melons and the presence of contamination. No power was given in this test.

## Discussion

### Significance of results

The results from this research have shown that washing a cantaloupe rind that was contaminated is sufficient to prevent the transferring of the bacteria from the rind to the flesh. In order to show that the bacteria were able to transfer from the rind to flesh when it the melon was cut, a positive control was used where the melon was inoculated and not washed. With these findings, a further discussion can be made from the results.

### Comparison to literature reviews

The CFIA (2012) mentioned that the characteristic of the rind provides areas for bacterial attachment and protection from cleaning and sanitization. This challenge was the reason why the data in the “washed” column showed many melons that had the presence of the bacteria even after being washed.

Similar to Ukuku and Sapers (2001) who found that the survival and transfer of *Salmonella* was positive on fresh cut pieces of melon, the author from this study found that *E.coli* was also able to transfer from the rind to the flesh of the melons.

Researchers, Ukuku *et al.* (2004) and Bhagwhat (2006), have found that the use of hot water and the mechanical movement of a brush under running water were effective ways to reduce the bacterial load on contaminated melon rinds. This method was replicated in the procedure of this study and showed that *E.coli* was successfully removed from the rind of the cantaloupes. The removal was justified by negative results in the EC broth tubes that tested for the presence and absence of fecal coliforms.

### Potential errors

A systematic error may have occurred during the cutting and transferring of melon flesh into stomacher bags. Due to time constraint and lab space availability, the experiment was done in a small area on a lab bench. There was a possibility for cross-contamination in the workspace, although precautions were taken to reduce the chances of any contamination. Some precautions included separating washed and unwashed melons, washing hands frequently, and sterilizing equipment as often as necessary.

### Alpha and beta

An alpha error is considered if the p-value falls in between 0.05 and 0.01. The p-value in this study was

0.035. In order to minimize the possible alpha error, the cut-off of alpha could be set at 0.01. If alpha was set as 0.01, then the null hypothesis would not have been rejected when the p-value was 0.035. A beta error may be present as a result when the p-value is insignificant and is close to the cut-off. In this alternate scenario, the number of samples will need to be increased in order to reduce beta error.

### Contribution of findings

The purpose of the study was to determine if *E. coli* is transferred into cantaloupe melon flesh when it is cut. The finding from this study raised awareness in regards to the importance of washing melon rinds and the direct role consumers have in preventing a foodborne illness.

## Recommendations

### Results

Based on these findings, it is recommended that cantaloupe melons are washed before they are cut for human consumption. There was statistical significance from the data that supported the washing of melon to prevent further contamination. In fact, it is difficult to determine whether a melon rind is contaminated or not until an actual outbreak occurs or if someone falls ill. The best method of prevention is to clean the melon rinds.

However, if an outbreak was present then regular cleaning may not be sufficient to prevent further pathogenic transfer from the rind to the flesh. The reason is because this study was not able to determine the actual amount of bacteria that was transferred. So it is difficult to conclude if washing was effective in removing or reducing the pathogen to safe enough levels to consume. As well, some pathogens may have a low infectious dose and cleaning may not necessarily remove all pathogens.

## Limitations

### Media

The EC medium used was designed to test for the presence of fecal coliforms, but not *E. coli* specifically. If budget had permitted, VRBA with MUG or EC medium with MUG would have been a better medium to use. These media specifically test for *E. coli* and the agar allows for enumeration.

## Quantitative vs. Qualitative

A qualitative measure can only measure the presence and absence of the fecal coliform that transfers on to the flesh. It is a limitation of this study because it cannot quantify the amount of *E. coli* that was transferred. The LST broth used in this study enriches any amount of bacteria that was transferred on to the melon flesh; therefore, even if the concentration on the melon flesh was insufficient to cause a foodborne illness, the results would have still shown a positive for *E. coli*. The qualitative results can only be used to conclude whether washing was effective in preventing the transfer of *E. coli* into melon flesh when it is cut.

## Sample Size

Instead of using individual melons as one sample, the author had to divide each melon into four sub-samples due to budget constraints. Each sub-sample counted as one sample in the experiment. The problem was that if one rind was contaminated it would then be highly likely for the other quarters to be contaminated from the same knife blade cutting through. To reduce the chance of this occurring, the knives were sterilized with 70% isopropyl alcohol and flamed before each cut was made into the melon.

In addition, another problem with the sample size was the amount of melon that was collected from each quarter. The amount of 25g may not necessarily be representative of the entire sample that was much larger than 25g.

## Fisher's Exact Test

With expected values of  $\leq 2$  in two cells, the Fisher's exact results could be read. In this case, the P-value would become 0.106 and therefore not statistically significant. Increasing the sample size would confirm these findings.

## Future research

For future studies, the author recommends doing a quantitative analysis to determine whether a sufficient concentration of potential pathogens is transferred from the rind into the melon flesh to cause illness. As mentioned in the limitations, a quantitative measure would give a better representation of the effectiveness of washing the rind.

## Conclusions

The purpose of this research was to perform a presence and absence test to determine if inoculated *E. coli* is transferred into cantaloupe melon flesh when it is cut, by comparing washed and unwashed contaminated melons. The null hypothesis for this study was that there is no association between washing a contaminated cantaloupe melon and the presence of the contamination in the flesh.

In this study, the author was able to reject the null hypothesis and conclude that there was an association between washing a melon and the presence of *E. coli* in the melon flesh. The results have shown that washing is effective in preventing the presence of *E. coli* due to a transfer from a contaminated rind. The role of an Environmental Health Officer may include educating the public in properly storing and cleaning melons before they are consumed.

## Acknowledgements

The completion of this document and research was made possible through the financial contribution from the British Columbia Institute of Technology. Additional thanks are given to Helen Heacock and Bobby Sidhu for their comments and editing as well as Ken Keilbart and Melinda Lee for laboratory assistance and support.

## Competing interests

The author declares that they have no competing interests in the completion of this research.
